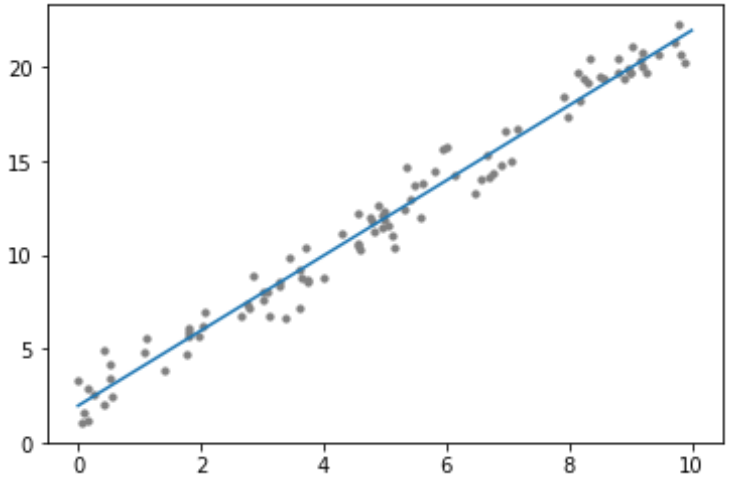
# Linear regression

- Linear model to predict a single real value based on some input features

$$f(\mathbf{x}) = w_0 + \mathbf{w}^T\mathbf{x} = w_0 + w_1x_1 + w_2x_2 + \ldots + w_nx_n$$

- Simple linear regression (1 input feature)

$$f(\mathbf{x}) = w_1x_1 + w_0$$

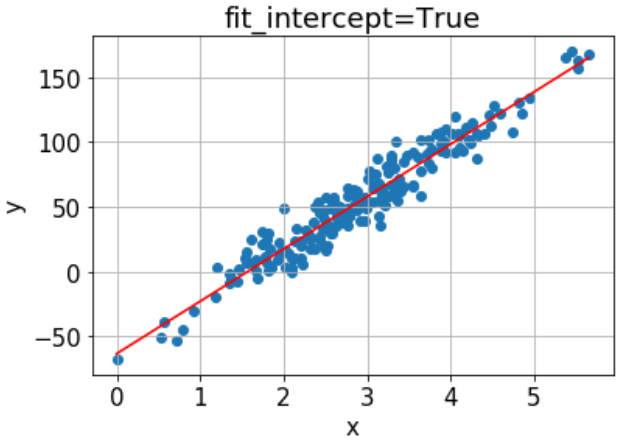


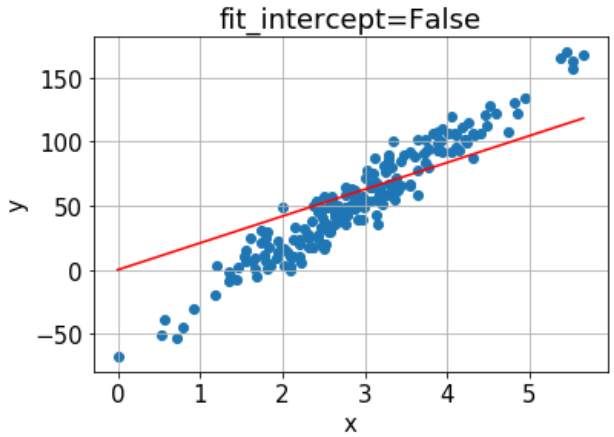
# Linear regression

- Regression with Scikit-learn

```
from sklearn.linear_model import LinearRegression
reg = LinearRegression(fit_intercept = True)
reg.fit(X_train, y_train)
y_test_pred = reg.predict(X_test)
```

- The hyperparameter **fit_intercept** specifies whether the intercept will be computed during training
  - Default is True





# Evaluating regression

PoliTo DBMG

- Evaluation metrics for regression:
  - MAE (Mean Absolute Error)
  - MSE (Mean Squared Error)
  - $R^2$
- Evaluated by comparing the two vectors
  - y_test ($y$): the expected result (**ground truth**)
  - y_test_pred ($\hat{y}$): the prediction made by your model

# Evaluating regression

- MAE (Mean Absolute Error)

$$MAE = \frac{1}{n}\sum_{i}|y_i - \hat{y}_i|$$

- MSE (Mean Squared Error)

$$MSE = \frac{1}{n}\sum_{i}(y_i - \hat{y}_i)^2$$

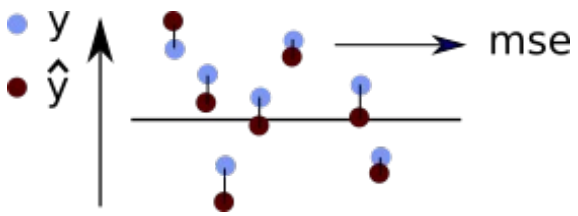
- Both positive numbers
  - MSE tends to penalize less errors close to 0

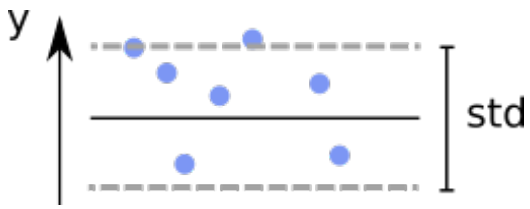
# Evaluating regression

- $R^2$ (R squared)
  - It represents the proportion of variance explained by the predictions

$$R^2 = 1 - \frac{MSE}{std^2}$$

  - $R^2$ is close to 1 when you have good predictions
  - $R^2$ **negative** or **close to 0** means wrong predictions





# Evaluating regression

- Evaluating regression with Scikit-learn

```
from sklearn.metrics import r2_score
from sklearn.metrics import mean_absolute_error
from sklearn.metrics import mean_squared_error

# Compute R2, MAE and MSE:
r2 = r2_score(y_test, y_test_pred)
mae = mean_absolute_error(y_test, y_test_pred)
mse = mean_squared_error(y_test, y_test_pred)
```

# Evaluating regression

PoliTo DBMG

- Evaluation with cross_val_score()

```
from sklearn.model_selection import cross_val_score

reg = LinearRegression()
r2 = cross_val_score(reg, X, y, cv=5, scoring='r2')
```

- Parameters:
  - cv = number of partitions for cross-validation
  - scoring = scoring function for the evaluation
    - E.g. 'r2', '**neg**_mean_squared_error'
- Similarly, we can use cross_val_predict()

# Notebook Examples

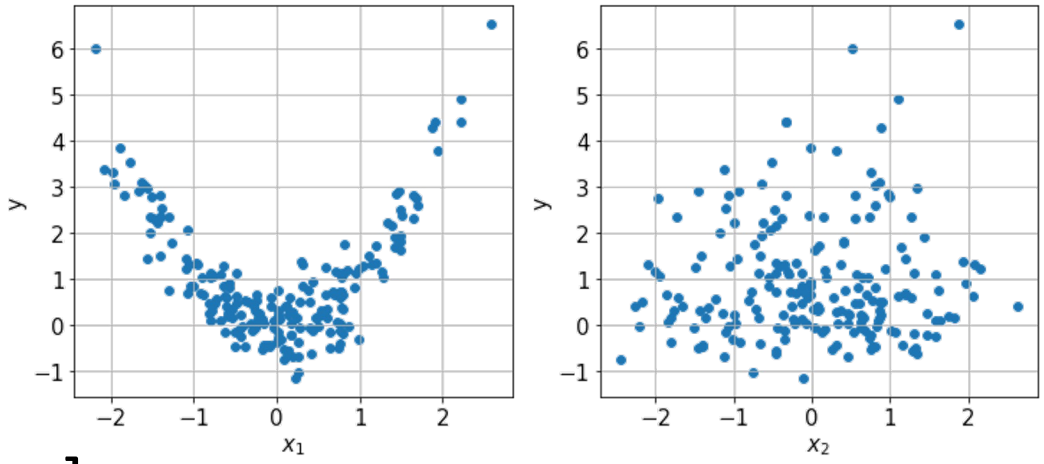
- 4b-Scikitlearn-Linear-Regression.ipynb
  - 1. Simple linear regression
  - 2. Linear regression with multiple input features

# Polynomial regression

- Polynomial regression
  - Useful when the data does not follow a linear trend
- **It consists of:**
  - Computing new **features** that are power functions of the input features
  - Applying **linear** regression on the new features

# Polynomial regression

- Example



input vector = $[x_1, x_2]$

degree(2) features = $[1, x_1, x_2, x_1^2, x_2^2, x_1x_2]$

$f(x) = w_0 + w_1x_1 + w_2x_2 + w_3x_1^2 + w_4x_2^2 + w_5x_1x_2$

# Polynomial regression

- Extracting polynomial features

```
from sklearn.preprocessing import PolynomialFeatures
poly = PolynomialFeatures(5)
X_poly = poly.fit_transform(X)
```

- Input
  - degree
    - Integer: the maximal degree of the computed features
    - Tuple: min and max degrees of the computed features
  - interaction_only: if True, only include interactions
  - include_bias: if True, add a bias column (column of ones)
- Output (of fit_transform())
  - A 2D **NumPy array** with the new feature matrix

# Polynomial regression

- Building a **pipeline** with polynomial features and linear regression

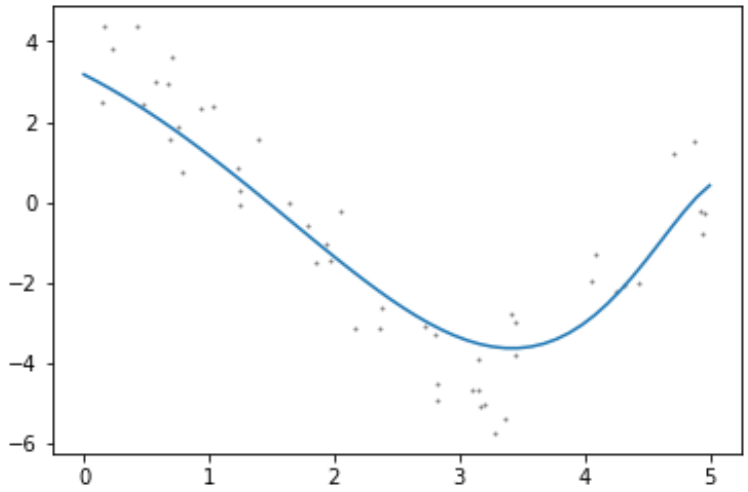
```
from sklearn.pipeline import make_pipeline
reg = make_pipeline(PolynomialFeatures(5), LinearRegression())
reg.fit(X_train, y_train)
y_test_pred = ret.predict(X_test)
```

- Pipelines are objects that allow concatenating multiple Scikit-learn models

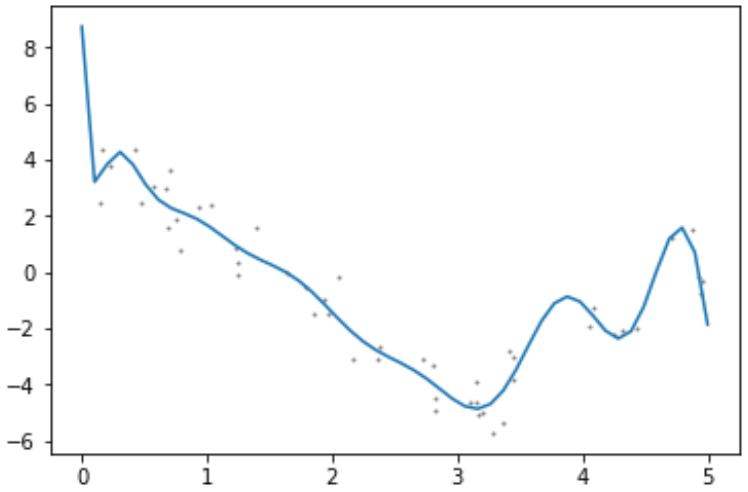
# Polynomial regression

- Higher polynomial degree means higher **capacity** of your model, but …
  - Pay attention to not **overfit** your data
  - Overfitting occurs in these cases when you have few samples and a model that has high capacity

Correct regression



Overfitting



# Polynomial regression

- To avoid this form of overfitting
  - Use more training data (if possible)
  - Use lower model complexity (capacity)
  - Use regularization techniques
    - E.g. Ridge, Lasso

# Polynomial regression

- **Ridge** and **Lasso** are two techniques for training a linear regression (or a linear regression with polynomial features)
- They try to assign values **closer to zero** to the coefficients assigned to features that are not useful for the regression
- This effect can **decrease the complexity** of the model when necessary

# Polynomial regression

- When training normal linear regression you **minimize the MSE** to compute the coefficients
- When training **Ridge** you minimize

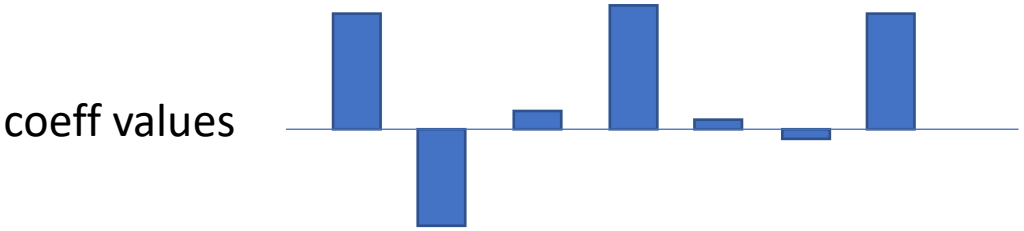
$$MSE + \alpha(\sum_i w_i^2)$$

- When training **Lasso** you minimize

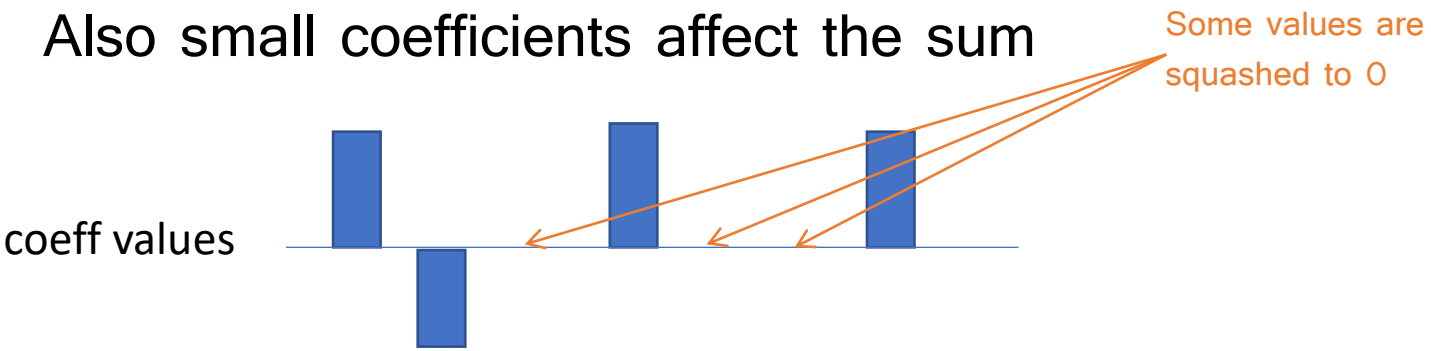
$$MSE + \alpha(\sum_i |w_i|)$$

# Polynomial regression

- **Ridge** tends to lower uniformly all the coefficients
  - Coefficients already close to 0 have little effect on the sum of **squares** (if $x \approx 0$, $x^2 < x$)



- **Lasso** tends to assign the value 0 to **some** coefficients (feature selection)
  - Also small coefficients affect the sum



# Polynomial regression

- **Ridge:**

```
from sklearn.linear_model import Ridge
reg = Ridge(alpha=0.5)
```

- **Lasso:**

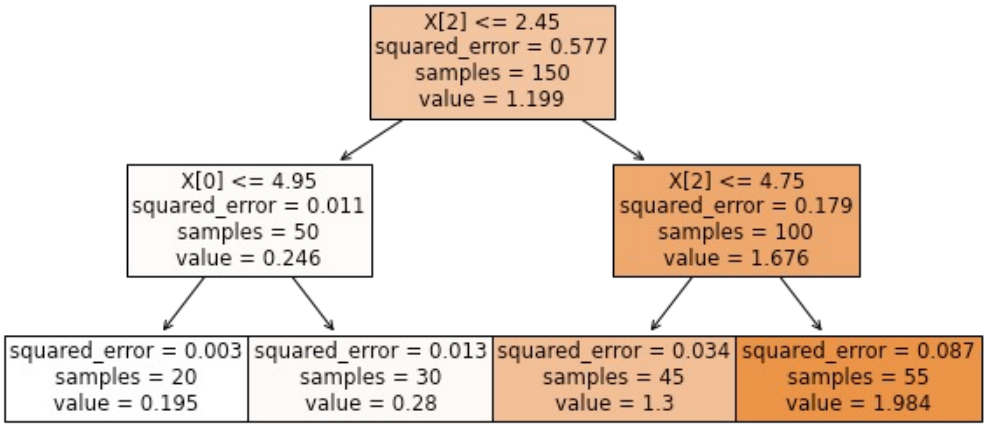
```
from sklearn.linear_model import Lasso
reg = Lasso(alpha=0.5)
```

# Notebook Examples

- 4c-Scikitlearn-Polynomial-Regression.ipynb
  - 1. Polynomial regression
  - 2. Overfitting and regularization

# Tree-based regression

- Like decision trees, but:
  - Real values used as targets instead of classes
  - Node impurity computed as variance
  - Each leaf assigns average value of points in it

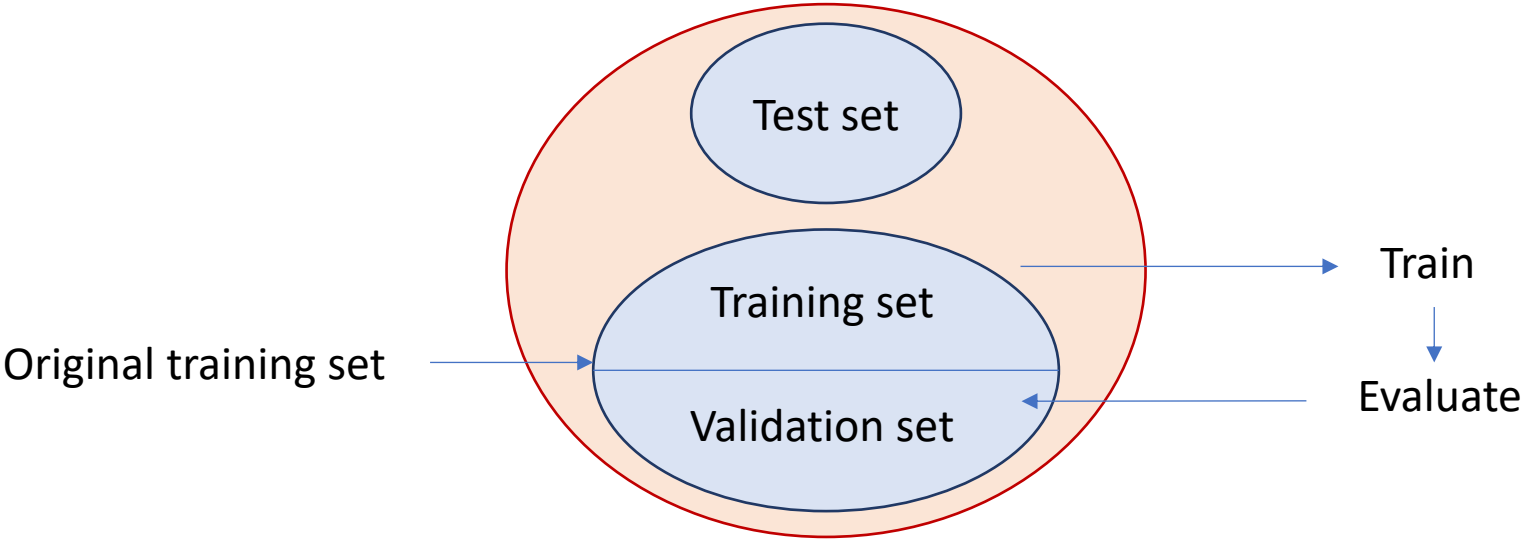


# Hyperparameters selection

- Hyperparameters vs parameters
  - Hyperparameters are selected by the user
  - Parameters are computed by the algorithm during training
- **Important**: hyperparameters cannot be set by finding the values that give the best results on the test set
  - This methodology **will overfit the test set**
  - We would be using **information from the test data** to select some **training** hyperparameters

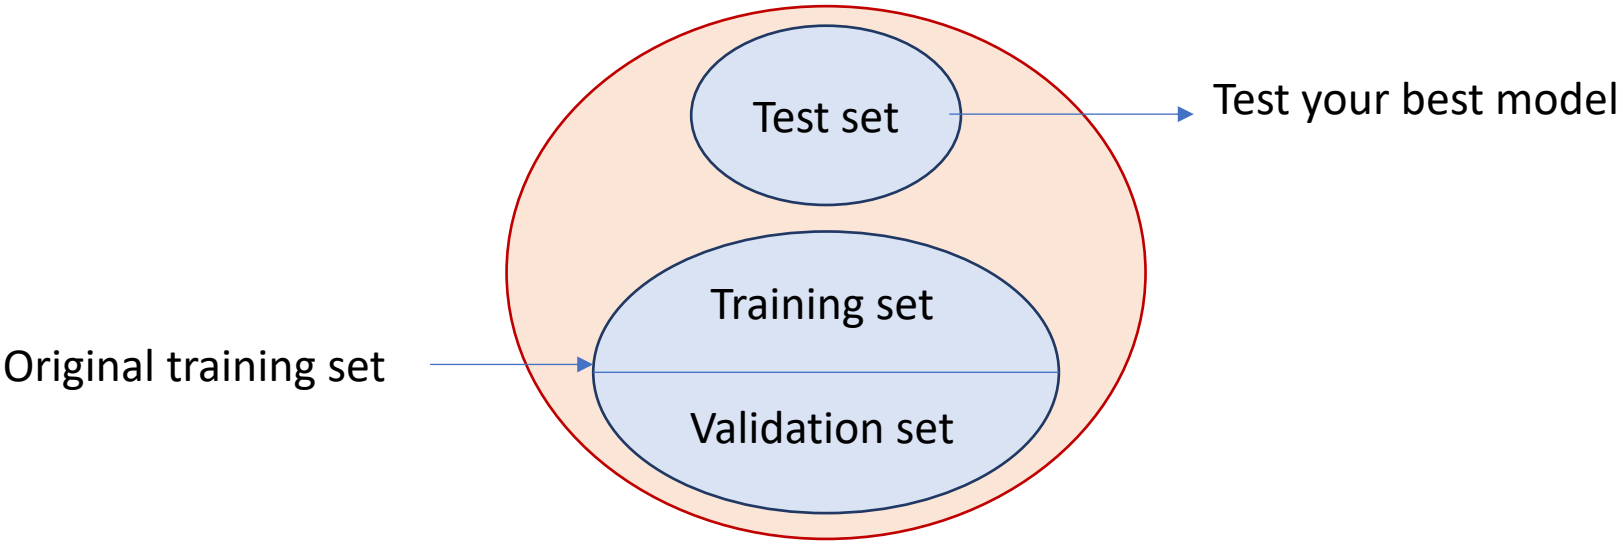
# Hyperparameters selection

- There are two valid methodologies
- 1. Use hold-out to divide training data in 2 parts
  - Fit different model configurations on the **training** set
  - Pick the best one by evaluating the performance on the **validation** set



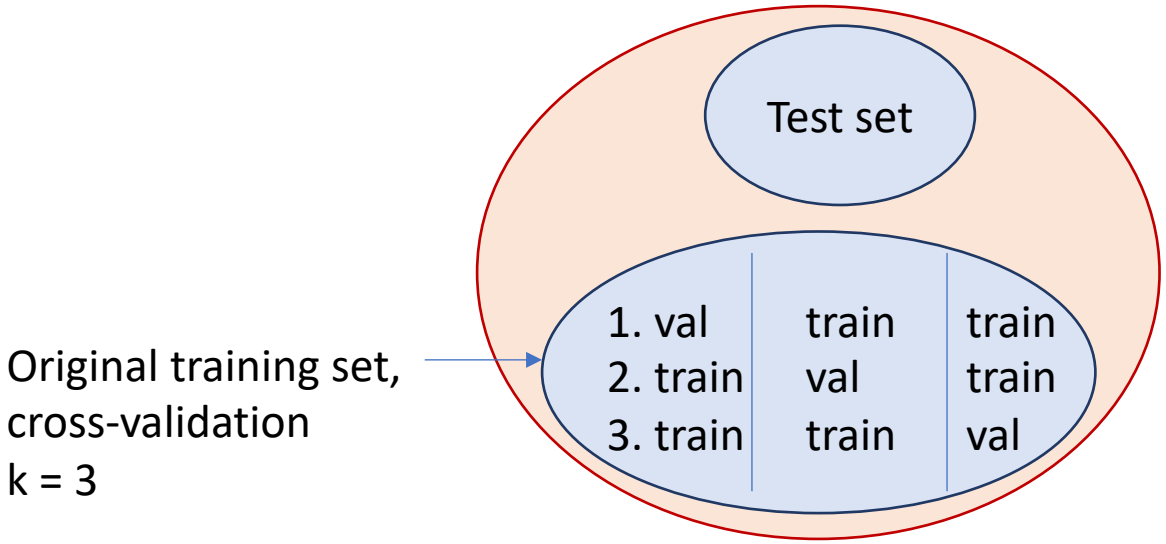
# Hyperparameters selection

- Finally test the selected model on the actual **test set** to have a measure of how well the selected hyperparameters work with new data



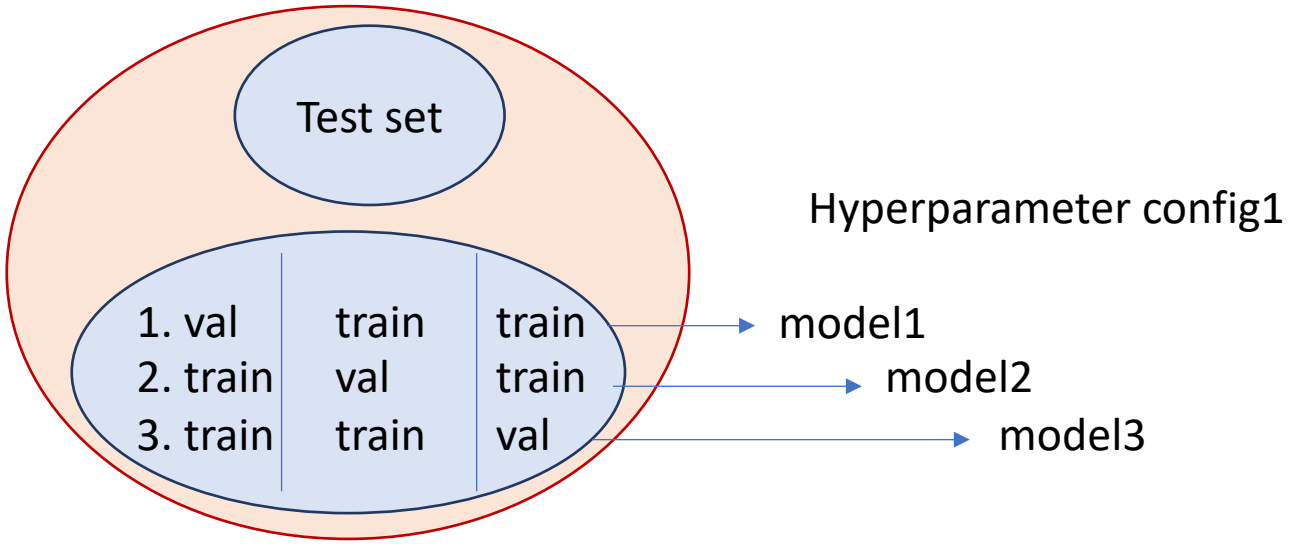
# Hyperparameters selection

- 2. Use cross-validation (k-fold) on training data
  - At each **iteration** 1 partition of the training data is used as **validation** set, the others are used to **train** the models



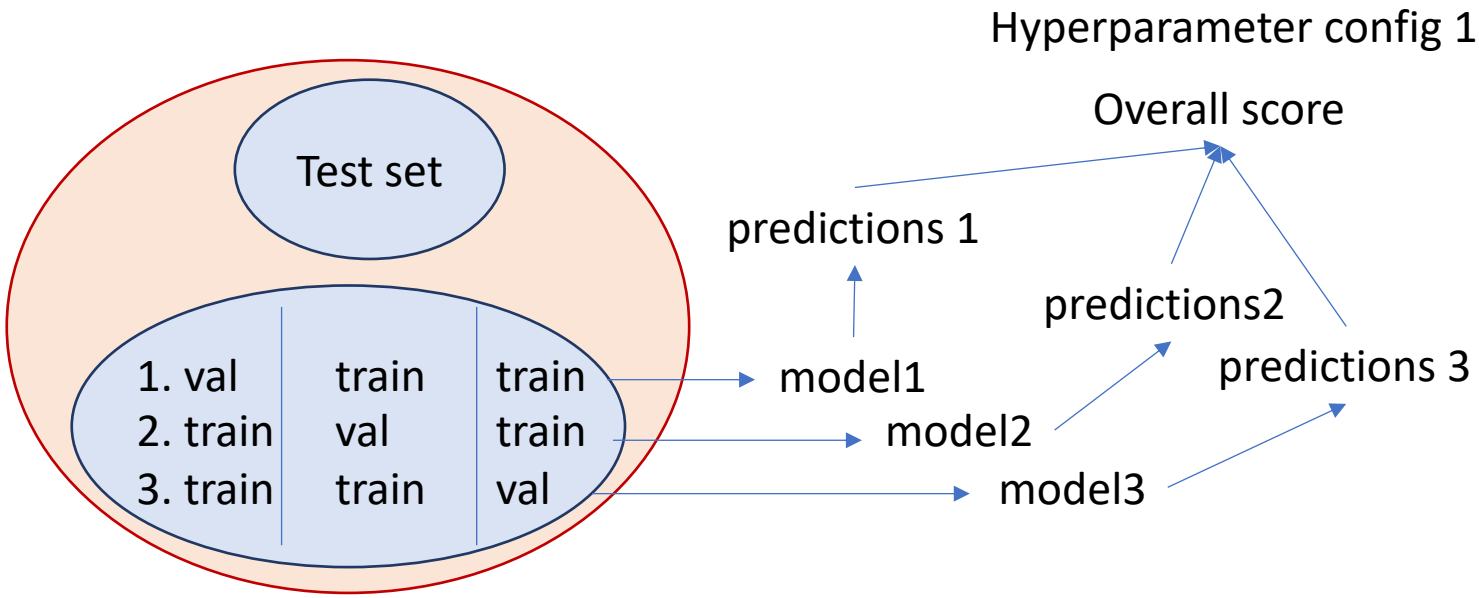
# Hyperparameters selection

- 2. Use cross-validation (k-fold) on training data
  - For a given **configuration** we train k **models** on the training partitions and evaluate them on the **validation** partition



# Hyperparameters selection

- 2. Use cross-validation (k-fold) on training data
  - For each model configuration compute the **overall** scores on the validation partitions
  - Select the configuration with the **highest** overall score



# Hyperparameters selection

PoliTo DBMG

- This second methodology can be easily performed in Scikit-learn
  - First define a **dictionary** with the **parameter values** that you want to tune
  - E.g. for Ridge regression:

```
param_grid = {'alpha' : [0.1, 0.2],
              'fit_intercept' : [True, False]}
```

  - With this grid Scikit-learn will try all the **combinations**:
    - {alpha=0.1,fit_intercept=True}
    - {alpha=0.1,fit_intercept=False}
    - {alpha=0.2,fit_intercept=True}
    - {alpha=0.2,fit_intercept=False}
  - ParameterGrid() enumerates all these combinations

# Hyperparameters selection

- Then define a model and call GridSearchCV

```
from sklearn.model_selection import GridSearchCV
reg = Ridge()
gridsearch = GridSearchCV(reg, param_grid, scoring='r2', cv=5)
gridsearch.fit(X_train, y_train)
```

- This code will pick the best configuration of the param grid, for Ridge model,
  - According to the $\mathbf{R^2}$ score
  - Using a cross validation with **k=5** partitions

# Hyperparameters selection

- The best parameter configuration can be found in the *best_params_* attribute of the gridsearch object
- An instance of the model with the best configuration is available in best_estimator_
  - **Important**: it is trained on the **whole dataset**!

```
...
gridsearch.fit(X_train, y_train)
print(gridsearch.best_params_['alpha'])
print(gridsearch.best_params_['fit_intercept')

best_configured_model = gridsearch.best_estimator_
```

# Notebook Examples
